The mention of commercial products, their source, or their use in connection with material reported herein is not to be construed as either an actual or implied endorsement of such products.

ABSTRACT

An inventory was conducted of the average annual emissions of air pollutants; NO_X, SO_X, CO, particulate matter and hydrocarbons; from oil production operations in the state of California. The emissions were generated on a lease-by-lease basis and aggregated and reported by (1) oil field (with associated geographical location), (2) County, and (3) Air Basin. Preparation of this emission inventory involved field surveys of representative production sites for equipment inventorying; field tests of oil field IC engines and heaters for emission factor development; and processing of extensive data from the California Division of Oil and Gas, the American Petroleum Institute, and other sources for emissions calculation.

On the basis of this program it was concluded that the emissions from oil production in California are a significant portion of the total emissions from stationary sources. In the South Coast Air Basin alone, oil production accounted for 18 percent of the CO, over 3 percent of the NO_{χ} , over 3 percent of the hydrocarbons and less than 1 percent of the particulate stationary sources emissions during the 1979 study year.

SECTION 1.0

BACKGROUND

Crude oil production in California is a significant air pollution emission source. A 1976 inventory conducted by KVB showed 5 percent of the total hydrocarbon emissions in the South Coast Air Basin resulted from crude oil production. In addition to these fugitive hydrocarbons, the engines, heaters, steamers and fireflooding operations in the oil fields produce considerable quantities of nitrogen oxides, sulfur oxides and fine particulate matter.

There were approximately 230 active oil fields and over 43,000 oil wells in California when this program began in 1979, some located in very remote locations. While the California Division of Oil and Gas (DOG) regulates the various oil production operations and maintains location and production data for each well, there was very little information available concerning the type or quantity of equipment located at each site. There are many oil production companies ranging in size from the "major" oil companies to small independent producers who may own only one oil well. In addition, there are many small independent companies who specialize in well drilling, remedial work and welding services as subcontractors to these oil production companies.

The ARB in their continuing effort to upgrade the statewide emissions inventory and provide assistance to the local air pollution control agencies engaged KVB in 1979 to inventory the emissions from primary and secondary oil production. In 1981 the program was expanded to include tertiary or thermally exhanced production. There was a program hold of approximately one year while funding for the latter segment was obtained.

California is the fourth largest producer of crude oil in the United States. As such, the petroleum industry is an important contributor to the state's economy. The industry can be expected to grow in California as

production of the vast heavy oil reserves is increased due to the development of improved recovery techniques and economic incentives.

SECTION 2.0

OBJECTIVES

The primary objective of this program has been to quantify the average annual hydrocarbon, NO_{X} , SO_{X} , CO and particulate emissions associated with oil recovery and gas processing for the State of California on an oil field or gas plant, county, air basin and statewide basis. California's oil producing activities are concentrated in the counties of Orange, Los Angeles, Monterey, San Luis Obispo, Santa Barbara, Venture, Kern and Fresno as well as offshore production locations in state and federal waters.

SECTION 3.0

PROGRAM APPROACH

As in any inventory program the basic approach is to locate and identify emission sources and apply suitable emission factors to compute and then categorize the emissions. Because there are so many individual sources of oil production emissions (43,000 oil wells in approximately 230 fields) it was necessary to use sampling procedures in order to develop both the number of sources and emission factors. Realize that in California there are over 1.5 million oil field valves and three million oil field fittings. Various techniques can be used to complete existing information from which emissions could be determined. This section summarizes the general approach taken by KVB.

As stated above, the primary objective of the inventory was to compile emissions of the five criteria pollutants, NO_{X} , SO_{X} , particulate, THC, and CO by oil field or gas plant, county, air basin, and state. To ensure that a proper representation of oil field characteristics and operations were incorporated in the sampling process, oil fields were grouped according to specific parameters. Representative fields from each group were then selected

for inventory. The inventory procedures were further refined by inventorying specific leases at each field. The lease was the lowest level on which data were compiled.

KVB crews visited over 30 oil production sites including offshore platforms, production islands and gas plants. These sites were systematically selected as representative of various oil leases in the state. Detailed counts were made of valves, fittings, and surface equipment associated with petroleum production or gas processing. The estimated 2,500 leases in the state were segregated into ten categories. For each of the ten categories, unique emissions models or algorithms were prepared. The emissions for each respective lease in that category were then determined based on the number of wells and throughput rate for that lease. Two other category models were developed which covered the special cases of (1) gas plants, and (2) onshore treatment facilities which receive crude and gas produced by the offshore platforms.

These lease category models were constructed using the following procedure. Fugitive hydrocarbon emissions from sources including valves, fittings, sumps, pits, mechanical oil/water separators, compressors, etc. were quantified on a lease-by-lease basis using the appropriate lease algorithm along with the number of wells on that lease. These fugitive-hydrocarbon sources were inventoried at each production survey site by type (i.e., globe valve, threaded fitting, rotary seal...etc.). Using the hydrocarbon leakage rate data published by the American Petroleum Institute (API) (Ref. 1) the total emissions per hardware item category (i.e. valve, fitting sumps, etc.) was obtained. Summing the emissions from all sources in a particular hardware item category for the production sites surveyed within a lease model group and dividing by the total number of wells surveyed in that group produced an emission algorithm for each hardware item category in units of lb/day of emissions per well. These hardware item algorithms were then summed to obtain a unique model for that lease which included emissions from valves, fittings, pumps, compressors, etc. Then, to estimate the fugitive hydrocarbon emissions from a given lease, the number of wells for that lease was multiplied by that unique lease model parameter.

Tank breathing loss and working loss emissions were calculated as a function of production rate or annual throughput. Based on a model developed from a statistical sampling of lease tank capacities versus annual production rates, the tank capacity for each lease was determined. The lease tankage, in a given field was summed to find total tankage which was used to determine annual breathing loss emissions. The total field production rate was used to determine working loss emissions. These emissions were calculated from algorithms developed from the AP-42 fixed-roof tank emission equations and tankage characteristics specific to the oil fields. Separate algorithms were used for tankage with and without vapor control.

Steam generators, heater treaters, boilers, fire floods and IC engines were inventoried on a field rather than lease basis. The statistical basis for these were IC engine count; heater treater, steam generator and boiler capacity or rated heat input rate; plus incremental oil production rate resulting from fireflooding operations. Emission factors for the various emission sources were developed from (1) KVB's field testing program (conducted under this contract), (2) AP-42, and (3) KVB's tertiary oil recovery report (Ref. 2), previously prepared for ARB.

A computer program, written for this project, aggregated the emissions from each of those sources by field, county...etc. Emissions calculated by the program were expressed as metric tons/year. Each field was located by up to six Universal Transverse Mercator (UTM) coordinates.

SECTION 4.0

SUMMARY OF RESULTS

4.1 TOTAL ANNUAL EMISSIONS

The primary results obtained in this program were a quantification of NO_X, SO_X, THC, particulate, and CO emissions associated with oil production and gas processing on a field or gas plant, county, air basin and statewide basis. These emissions included those from Fresno, Kern, Orange, Los Angeles, San Luis Obispo, Monterey, Santa Barbara, and Ventura Counties and the offshore producing locations in state and federal waters. These areas include

nearly all the major oil fields in the state. The total annual emissions in metric tons for each facility by county are presented in Table 1. The emissions by air basin and emission category are presented in Tables 2 through 5. The total statewide emissions associated with petroleum production based on the eight-study counties are presented in Table 6.

Aggregated in this table are emissions associated with tanks, well cellars, sumps and pits, valves, fittings, well heads, pumps, compressors, IC engines, heater treaters, steamers and boilers, mechanical oil/water separators, fireflooding, and flares. Not included, as explained below, are emissions associated with oil well drilling and steam enhanced oil recovery well vent emissions.

On the basis of these results, it can be seen that emissions from oil production are a significant portion of the total emissions from stationary sources in California. Table 7 compares the South Coast Air Basin emissions for petroleum production as estimated by this program to the Draft 1979 Stationary Source Emissions Inventory prepared by the South Coast Air Quality Management District.

4.2 DRILLING RIGS

Drilling rig emissions were calculated on a regional basis rather then a field by field basis. This approach more accurately estimates the total annual emissions and eliminates wide fluctuations which might occur in a given field from year to year due to increases or decreases in drilling activity. Further, the regional approach also accounts for "wildcatting" and other drilling which occurs outside specific oil field boundaries. The results of the analysis for the year 1979 are presented in Table 8.

Drilling in California is done by electric, gas and diesel powered rigs. In the course of drilling an oil well, a rig's power plant will vary between idle and full load depending upon depth, hardness of formation and whether the rig is drilling or performing some other operation. The approach used by KVB was to plot the fuel used per day and the days required to drill

for various depth wells in the San Joaquin Valley, Coastal Area, and the Los Angeles Basin. This integrated the many cycle fluctuations involved in drilling a well.

To calculate emissions it was necessary to first determine the average depth well drilled in each region. From that the total amount of equivalent diesel fuel required could be found from the graphs of fuel per day and time required versus depth. This was apportioned into diesel fuel and natural gas using the horsepower ratios of the rigs located in each region. A correction was also made for electrically driven rigs. The emissions were then calculated using AP-42 emission factors.

4.3 TERTIARY OIL RECOVERY WELL VENTS

Steam enhanced oil recovery well vents have been found to be significant sources of hydrocarbon emissions. These emissions can be controlled through the use of centralized vapor recovery systems, however, in many locations there is no control system used. Using recently published data, prepared by Radian for EPA (Ref. 3), KVB has analyzed the volatile organic compound (VOC) emissions resulting from these well vents on a field-by-field basis. These emissions are reported separately and were not included in the computer program as VOC's were not compatible with the computer program and the emissions data became available after the computer program had been written. The emissions are summarized in Table 9.

4.4 IC ENGINE EMISSION FACTORS

During the test phase of this program, KVB found wide variations in engine operating conditions and emission levels of CO, NO_X, and THC. The findings suggest that there is no single correlation between the emission levels and any specific operating parameter. However, using the results from testing 22 IC engines, a set of overall emission factors was developed. These are presented in Table 10.

*Results based on tests run on 22 pas-fired internal combustion engines; eight have HP ratings 5100 HP. Average engine load measured was 174, HP HB. Tests occurred at three different oil fields in the South Coast Air Basin. Fuel used was either natural gas or processed field gas.

tBased on a typical natural gas sulfur content of 2000 grains per 10⁶ acf as reported in AP-42, Section 1.4.1. (Even though lbs/hr is an emission rate and not an emission factor, it is provided here for convenience.

4.5 FIELD HEATER EMISSION FACTORS

Tests conducted on eight oil field heaters and heater treaters indicate that $\mathrm{NO}_{\mathbf{X}}$ emission levels are low. The test results also showed that the levels of CO, THC and carbon (Bacharach Smoke Spot Number) could be quite high due to either a combustion air excess or deficiency resulting from poor tuning or partially plugged air inlets. Composite emission factors for the eight heaters are presented in Table 11.

SECTION 5.0

CONCLUSIONS

This program has resulted in a comprehensive emission inventory for the oil production industry in California for the year 1979. In addition, a computerized emissions data base has been compiled which with the developed methodology can be updated annually.

SECTION 6.0

RECOMMENDATIONS

For the most part, housekeeping at the sites visited was relatively good and at several sites it was impressive. There were several sites which were in need of cleanup and valve and fitting maintenance. Oil leaks and spills and poorly maintained piping and equipment contribute significantly to fugitive hydrocarbon emissions. Valve and fitting maintenance requirements developed jointly by the oil industry and the air regulatory agencies and the sump and pit reduction program conducted by the Division of Oil and Gas should significantly reduce fugitive emissions. Additionally, general housekeeping and maintenance of equipment such as tanks needs to be encouraged. Well vents currenty release large amounts of VOC emissions. These quantities will increase as the use of thermally enhanced production increases. These emissions should be controlled both from an air quality and a product loss standpoint.

*Results indicate average emission factors developed from the testing of two 6-MMHtu/hr total, one 10-MMBtu/hr total, and one 8-MMHtu/hr total burner/liretube horizontal crude oil (oil-water emulsion) heaters. Fourteen tests on 6 burners over a fitting rate range of 20% to 80% of capacity were performed. Fuel was either processed field or natural gas.

**Based on a HIV of approximately 1,000 Btu/scf.

fPilot light tests were performed on each burner of a dual burner heater.

Mesults indicate average emission factors developed from the testing of two 500,000-Btu/hr single burner/firetube horizontal crude oil heater-treater and one 348,000 Btu/hr single burner/firetube, glycol reboiler. Five tests at approximately 40 to 80% load were performed. Fuel was processed field gas.

fResults based on the data obtained from one test performed at approximately 50% load. Heater is rated at 500,000 Btu/hr, fired on LPG, and of a single burner.

There is a lack of comprehensive test derived emission factors for valves, fittings and other components associated with heavy oil production. Heavy oil production is growing in California due to improved recovery technology and a changing economic climate. Hence, an emissions testing program similar to that conducted by Rockwell for API should be performed to establish emissions data for equipment associated with heavy oil production.

Shortcuts were used in this program to estimate emissions from tanks and sumps because data and methodologies required to perform more specific estimates of these emissions are not available at this time. While tanks are a significant source of hydrocarbon emissions, adequate estimating methods have not been developed so that emissions can be accurately assessed for even a single tank. This is considered a major research area which needs to be pursued by both regulatory agencies and industry.

It is recommended that the methodology and data base developed during this program be adopted as a foundation for future work.

SECTION 7.0

VALUE TO ARB'S RELEVANT REGULATORY PROGRAM

Data developed during the program in addition to upgrading the State's emission inventory data base also provides the inventory information necessary to revise and upgrade implementation strategies for the study counties, air basins, and the entire State. Emissions information from this program is available by pollutant and emission source category on a field or gas plant, county, air basin, and statewide basis. In addition, emissions associated with well vents and drilling rigs, which were not computerized, are presented on a field or regional basis.

Emissions information generated by this program for IC engines and drilling rigs provide pertinent input to the development and modification of emission control rules. Model rules for oil field valves and fittings and well vents have been prepared and are in various stages of implementation by the cognizant APCD's. The information developed by this project can be used to update the information base used to develop these rules.
